## Abstract

Objective. To assess whether abnormalities on functional magnetic resonance imaging (fMRI) are related to cognitive function in patients at presentation with clinically isolated syndrome (CIS) suggestive of MS.

Methods. Eighteen CIS patients and 15 healthy controls (HC) performed an adapted fMRI version of the Paced Auditory Serial Addition Test (PASAT). According to their PASAT performance, CIS patients were divided into two groups: 10 with a low PASAT performance ( $< 1SD$  from the mean value of HC) were considered “cognitive impairment” (CI); 8 patients were defined as “cognitively preserved” (CP). Between-group differences in the patterns of brain activations and effective connectivity were assessed.

Results. During PASAT, compared to HC, CIS patients showed increased activations of the bilateral inferior parietal lobe (IPL), bilateral precuneus, bilateral middle frontal gyrus (MFG), left anterior cingulate cortex (ACC), left claustrum, right thalamus and right caudate nucleus. When CIS patients were analyzed, the CI group had a more significant activation of the bilateral IPL than HC and CP patients. Compared to CP patients, they also had more significant recruitment of the right superior parietal lobe, right cerebellum, left MFG and left ACC. The analysis of effective connectivity showed stronger connections between several regions of the right hemisphere involved in working memory function in CI patients vs. CP and HC.

Conclusions. The observed differences in the patterns of cortical recruitment and connectivity in CI patients during PASAT performance are likely to be adaptive and have a role in limiting cognitive dysfunctions early in the course of MS.

## Introduction

In about 85% of patients with multiple sclerosis (MS), the clinical onset of the disease is a clinically isolated syndrome (CIS), involving the optic nerve, brainstem or spinal cord. Approximately 50-80% of these patients already have visible lesions on magnetic resonance imaging (MRI) scans, consistent with prior disease activity [1].

It is known that cognitive deficits play an important role in MS and that they impact significantly on patient activities of daily living and quality of life [2]. However, relatively little is known about the prevalence of cognitive impairment at the onset of the disease in CIS patients. Recent studies in this clinical population have described the presence of cognitive deficits ranging from mild to moderate, depending on the criteria used to define such an impairment [3,4,5,6].

Cognitive dysfunction in MS involves several domains including information processing speed, attention, memory and frontal executive functions [7]. This heterogeneity is usually not observed in individuals with CIS, in whom only deficits of information processing speed and working memory have been described [5]. A characterization of the cognitive profile of CIS patients as well as the mechanisms underlying the preservation of some cognitive functions in this condition might improve our understanding of the development of cognitive impairment in MS. Indeed, it has been recently demonstrated that cognitive deficits in CIS patients have a prognostic value to predict subsequent conversion to definite MS [8].

In relation to this, a valuable tool is represented by functional MRI (fMRI). In the last few years, fMRI studies have disclosed differences in the patterns of brain recruitment between MS patients and healthy controls (HC) when performing various active tasks. Some of these studies have suggested that, at least in some cases, an altered pattern of brain recruitment might contribute to limit the clinical consequences of tissue damage

1  
2  
3 [9,10,11]. Brain reorganization has also been observed in CIS patients when performing  
4 cognitive [12] and motor tasks [13]. To better characterize differences in the patterns of  
5 brain activations between MS patients and HC, a few studies have also analyzed  
6 functional/effective connectivity among different brain regions [14,15,16,17,18]. However,  
7 only a seminal study has shown an increased connectivity of brain regions of the working  
8 memory network in CIS compared to HC [19].

9  
10 To examine possible early fMRI cognition-associated abnormalities, we studied a  
11 sample of CIS patients using an adapted version of the Paced Auditory Serial Addition  
12 Test (PASAT), which has been previously applied in several fMRI studies of patients with  
13 definite MS [9,10,12]. This task is sensitive to abnormalities of working memory and  
14 information processing speed. In addition, to characterize further the possible differences  
15 in brain recruitment between CIS patients and HC, we also run an effective connectivity  
16 analysis to obtain a more complete picture of the functional abnormalities associated to  
17 cognitive performance in these patients.

## 18 **Materials and methods**

### 19 Participants

20 Eighteen right-handed patients at presentation with CIS suggestive of MS and  
21 paraclinical evidence of dissemination in space [20] were recruited consecutively at the  
22 Hospital Universitari La Fe and the Hospital Clinic Universitari MS Unit, Valencia, Spain.  
23 All patients were examined within 3 months from the first clinical episode and were free of  
24 steroids treatment for at least one month. Alternative neurological diseases were excluded  
25 by appropriate investigations [21, 22]. Exclusion criteria were concomitant therapy with  
26 antidepressants, psychoactive drugs, and a history of major medical, neurological or  
27 psychiatric disorders as well as drug and alcohol abuse. Depression was excluded with the

2  
3 Beck Depression Inventory (BDI). There were 10 women and eight men, and their mean  
4  
5 age was 32.9 years (range = 18-47 years). Oligoclonal bands were found in the  
6  
7 cerebrospinal fluid of all patients. Disability was rated using the Expanded Disability  
8  
9 Status Scale (EDSS) Score [23]. Fifteen aged-matched right-handed individuals with no  
10  
11 history of neurological or psychiatric diseases served as controls.  
12  
13

#### 14 15 Neuropsychological assessment

16  
17 Following neurological assessment and prior to the MRI acquisition, all participants  
18  
19 were assessed by an experienced neuropsychologist, blinded to clinical and MRI findings.  
20  
21 This assessment included the Brief Repeatable of Neuropsychological test (BRB-N)  
22  
23 validated in a Spanish population [24], the Matrix subtest included in the Wechsler Adult  
24  
25 Intelligence Scale III Battery (WAIS III) [25], which was used to match groups in term of  
26  
27 their intelligence quotients (IQ).  
28  
29  
30

#### 31 32 MRI acquisition

33  
34 Using a 3.0 Tesla scanner (Siemens Trio, Siemens, Erlangen, Germany), the  
35  
36 following sequences of the brain were acquired from all participants: 1) axial T2-weighted  
37  
38 fast spin echo (TR/TE = 6740/97; ETL = 15; FOV = 250 × 250 mm; matrix size = 256 ×  
39  
40 256; 40 contiguous slices; slice thickness = 3 mm); 2) axial echo-planar imaging (TR/TE =  
41  
42 3000/50 ms; flip angle = 90°; FOV = 250 × 250 mm; matrix size = 64 × 64; 29 contiguous  
43  
44 slices, slice thickness = 4.5 mm) during PASAT task.  
45  
46  
47

#### 48 49 Experimental Design

50  
51 Participants were instructed to perform the fMRI-adapted auditory PASAT task  
52  
53 [10]. PASAT consisted of a block design paradigm with 6 blocks of 1 min each: 3 for the  
54  
55 control condition and 3 for the active condition. In the PASAT task, a 1-digit number  
56  
57 between 1 and 9 was randomly presented every 3 s. During the control condition,  
58  
59 participants were instructed to repeat the last number heard. During the active condition,  
60

1  
2  
3 participants performed the PASAT task, which involved adding up the last two numbers  
4  
5 heard. Subjects were asked to give overt verbal responses, which were recorded by an  
6  
7 observer inside the scanner room. The stimuli for the tasks were presented using fMRI-  
8  
9 compatible headphones (VisuaStim, Resonance Technologies, Inc). The sound volume was  
10  
11 adjusted so that each participant could hear the stimuli of the PASAT test properly. Before  
12  
13 fMRI was performed, all subjects underwent a 10-minute practice session, which included  
14  
15 different stimuli presented in the scanner. Foam cushioning was used to immobilize their  
16  
17 head within the coil in order to minimize motion artifacts.  
18  
19  
20

### 21 22 Statistical analysis of clinical and cognitive data 23

24  
25 Statistical analysis was performed using the Statistical Software Package (Statsoft,  
26  
27 Inc). Inter-group comparisons were made in two steps. First, HC and CIS patients were  
28  
29 compared in term of their neuropsychological performance. This analysis showed no  
30  
31 difference between the two groups. As a second step, and as previously described [12], CIS  
32  
33 patients were divided into two groups according to their performance at PASAT, based on  
34  
35 the strategy suggested by Sepulcre et al. [24]: patients with PASAT performance 1SD  
36  
37 below the mean of HC were considered as cognitively impaired (CI) (n = 10). One-way  
38  
39 ANOVAs and the Fisher LSD post-hoc test were used to analyze the differences among  
40  
41 the three groups for clinical and cognitive data.  
42  
43  
44

### 45 46 MRI analysis 47

48  
49 All MRI postprocessing was performed by a single experienced observer, who was  
50  
51 unaware of subjects' identity. T2 lesions were identified and T2 lesion load (LL) measured  
52  
53 using the Jim software (Version 4.0, Xinapse Systems, Northants, UK,  
54  
55 <http://www.xinapse.com>).  
56  
57 fMRI data were analyzed using the Statistical Parametric Mapping (SPM5) software  
58  
59 (Wellcome Department of Cognitive Neurology, London, UK). Prior to the statistical  
60

1  
2  
3 analysis, all images were reoriented according to the anterior-posterior commissural line,  
4  
5 realigned to the first one, spatially normalized into the Montreal Neurological Institute  
6  
7 (MNI) space, and smoothed with an 8 mm Gaussian kernel filter. SPM calculation was  
8  
9 based on the General Linear Model [26]. The motion parameters estimated during  
10  
11 realignment were included in the statistical analysis as regressors. First-level task-related  
12  
13 contrast images were created for each subject and then used in a second-level random-  
14  
15 effect analysis (one-sample t-test) to define the brain patterns of recruitment in each group  
16  
17 separately (controls and CIS patients), using a threshold of  $p < 0.001$  family-wise error  
18  
19 (FDR) corrected, and a minimum cluster extent (k) of 20 contiguous voxels. Between-  
20  
21 group comparisons were assessed using a one-way ANOVA, with a threshold for  
22  
23 significance set at  $p < 0.05$  FDR corrected, with a minimum cluster extent (k) of 20  
24  
25 contiguous voxels.  
26  
27  
28  
29  
30

### 31 Effective connectivity analysis

32  
33 DCM is a mathematical framework which allows to characterize effective  
34  
35 connectivity, defined as the causal influence that one brain region exerts over another one  
36  
37 [27]. It requires defining an *a priori* model, usually chosen among possible alternative  
38  
39 models using a Bayesian model selection procedure [28]. In our case, this model was  
40  
41 established based on brain areas known to be related to working memory, as shown by  
42  
43 several previous fMRI studies [9,10,12]. The areas selected were: the left (L) and right (R)  
44  
45 middle third of the middle frontal gyrus (MFG), the L and R inferior frontal gyrus (IFG),  
46  
47 the L and R anterior cingulate cortex (ACC), and the L and R inferior parietal lobe (IPL).  
48  
49  
50 Using the VOI toolbox of SPM5, time series (adjusted for the effect of interest) were  
51  
52 extracted from a spherical volume (5 mm radius) centered at the most significant voxel  
53  
54 within each cluster of the SPMt map, displaying in each subject the brain areas active  
55  
56  
57  
58  
59  
60

1  
2  
3 during the PASAT task at  $p < 0.001$ , uncorrected. We assumed that the effect of the task  
4  
5 entered the network via the activation of the L MFG.  
6  
7

8 The Bayesian model selection [28] was performed to test which of the two possible  
9  
10 DCM models, including the previous areas, fitted better the data of the two study groups.  
11  
12 The first DCM model (M1) assumed a bilinear interconnection between all the above  
13  
14 mentioned areas. The second (M2) was identical to the model previously proposed by Au  
15  
16 Duong et al. [19], and considered only the connections shown in Figure 1 as possible  
17  
18 connections. The comparison of the two models showed that the M2 model was superior to  
19  
20 M1 in both HC (Bayesian factor [BF] of M1 =  $9.001 \times 10^{-66}$  vs. BF of M2 =  $1.111 \times 10^{65}$ ) and  
21  
22 CIS patients (BF of M1 =  $1.705 \times 10^{-11}$  vs. BF of M2 =  $1.132 \times 10^{112}$ ). As a consequence, the  
23  
24 intrinsic connectivity coefficients of M2 were estimated for each subject using a Bayesian  
25  
26 approach.  
27  
28  
29  
30

31 A multivariate analysis of variance (MANOVA) was used to examine inter-group  
32  
33 differences in the strength of connectivity of the previously estimated DCM coefficients.  
34  
35  
36  
37

## 38 Results

### 39 Demographic, clinical, neuropsychological and conventional MRI findings

40  
41 Table 1 summarizes the main demographic, clinical and conventional MRI findings  
42  
43 from CIS patients as well as their performance at PASAT. Table 2 presents the main  
44  
45 demographic, neuropsychological, and conventional MRI characteristics of the three study  
46  
47 groups.  
48  
49  
50

51 EDSS scores ( $p = 0.001$ ) and T2 LL ( $p = 0.03$ ) were significantly different between  
52  
53 CP and CI patients. CI patients did more errors at the behavioral PASAT task compared to  
54  
55 HC ( $p = 0.04$ ) and CP patients ( $p = 0.001$ ). Similar results were obtained when analyzing  
56  
57 the fMRI PASAT test ( $p = 0.04$  vs. HC, and  $p = 0.002$  vs. CP patients).  
58

a) *Within-group activations.* The results of within-group activations during the PASAT are summarized in Table 3 and illustrated in Figure 2. Both HC and CIS patients showed a recruitment of several areas in the frontal and parietal lobes, bilaterally, as well as areas that are part of the working memory network, bilaterally.

b) *Between-group comparisons.* During PASAT, compared to HC, CIS patients experienced a more significant recruitment of the bilateral IPL, bilateral precuneus, bilateral MFG, left ACC, left claustrum, right thalamus and right caudate nucleus. When CIS patients were analyzed according to their PASAT performance, the CI group had a more significant activation of the bilateral IPL than HC and CP patients. Compared to CP patients, they also had a more significant activation of the right superior parietal lobe, right cerebellum, left MFG and left ACC (Table 4, Figure 3). No areas were significantly more activated in CP patients *vs.* HC and CI patients.

c) *Analysis of effective connectivity.* Inter-group differences in the strength of connectivity coefficients are summarized in Table 5 and Figure 1. Compared to both HC and CP patients, CI patients had an increased connectivity between the: 1) R IFG and R IPL ( $p = 0.002$  *vs.* HC, and  $p = 0.0005$  *vs.* CP patients), 2) L IPL and R IPL ( $p = 0.008$  *vs.* HC, and  $p = 0.0005$  *vs.* CP patients), and 3) R IPL and R IFG ( $p = 0.003$  *vs.* HC, and  $p = 0.01$  *vs.* CP patients). Compared to CP, CI patients also experienced an increased connectivity between the: R ACC and R IPL ( $p = 0.009$ ), and R MFG and R IFG ( $p = 0.01$ ).

### **Discussion**

This study extends our knowledge about the functional changes which can occur in patients at presentation with a CIS suggestive of MS. To detect subtle changes in cognitive

1  
2  
3 functions, we used an adapted version of the PASAT, a task that assesses information  
4  
5 processing speed and working memory, since these functions are known to be altered in  
6  
7 these patients [5].  
8  
9

10  
11 In line with the results of previous studies [9,10,12], when compared to HC, CIS  
12  
13 patients showed an increased recruitment of several regions mainly located in the frontal  
14  
15 and parietal lobes, bilaterally. All of these regions contribute to different aspects of  
16  
17 working memory processing and the majority of them have been demonstrated to have a  
18  
19 load-dependent activity during working memory tasks [29,30].  
20  
21

22  
23 Notably, when CIS patients were subdivided into CI and CP according to their  
24  
25 PASAT performance, significant differences emerged between the study groups, not only  
26  
27 in the patterns of cortical recruitment, but also in the strengths of functional connections  
28  
29 among different brain areas. Compared to the other two groups, CI patients experienced an  
30  
31 increased recruitment of areas located in the IPL, bilaterally, which are known to be  
32  
33 involved in the maintenance and manipulation of a working memory information [31].  
34  
35 Compared to CP patients, they also experienced an additional recruitment of regions  
36  
37 located in the fronto-parietal lobes and cerebellum, which is known to be involved in high-  
38  
39 level cognitive functions and conflict adaptation [32]. It is worth noting that, in order to be  
40  
41 able to detect early markers of cognitive dysfunction in CIS, we defined as CI those  
42  
43 patients with 1 SD difference in PASAT performance with respect to the mean of HC  
44  
45 (while the cut-off usually applied is 2 or 1.5 SD). Our results indicate that, even in patients  
46  
47 with such a subclinical impairment, an increased pattern of cortical recruitment does occur,  
48  
49 probably reflecting an adaptive mechanism likely contributing to limit the clinical  
50  
51 consequences of disease-related tissue injury.  
52  
53  
54  
55  
56

57  
58 The analysis of effective connectivity, which was based on the model of brain  
59  
60 interconnections for PASAT performance previously proposed by Au Duong et al. [19],

1  
2  
3 allowed us to characterize better the pattern of fMRI abnormalities in CIS patients. In  
4  
5 particular, compared to CP, CI patients experienced stronger connections between the R  
6  
7 MFG and R IFG and between the R ACC and R IPL. They also had an increased  
8  
9 connectivity between the R IFG and R IPL and between the L and R IPL compared to both  
10  
11 CP patients and healthy controls, thus indicating an increased task demand for the R  
12  
13 hemisphere in these patients. The notion that an increased recruitment of areas of the R  
14  
15 hemisphere has a critical role for cognitive performance of MS patients agrees with  
16  
17 previous activation [33,9,34] and connectivity [14] studies performed in patients with CIS  
18  
19 and RRMS, as well as with several studies of the motor network (for a review, see Filippi  
20  
21 and Rocca [36], which showed that a recruitment of homologous regions of the two  
22  
23 hemispheres is one of the main compensatory mechanisms, at least at the earliest clinical  
24  
25 phases of the disease. Differently from previous studies, which found abnormalities of  
26  
27 brain recruitment in patients without overt clinical impairment [ 37, 38] our analysis did  
28  
29 not reveal any abnormality of activation and connectivity between CP CIS patients and  
30  
31 HC. Clearly, we can not exclude that our study was underpowered to detect such a  
32  
33 difference, considering the relatively small size of this group.  
34  
35  
36  
37  
38  
39

40  
41 In this study, we carefully selected a cohort of *de novo* CIS patients that were  
42  
43 studied within two months from the diagnosis. Even using such a strict criterion,  
44  
45 differences among CIS patients were found using fMRI. This is in line with the results of a  
46  
47 previous study of the motor system [38] which showed an increased recruitment of several  
48  
49 areas of the motor network in CIS patients assessed within three months from the onset of  
50  
51 the clinical symptomatology. Interestingly, compared to CP, CI patients also had a higher  
52  
53 EDSS score and T2 lesion load. These results strengthen the notion that CIS patients are a  
54  
55 heterogeneous population and call for a comprehensive characterization of functional and  
56  
57 structural MRI abnormalities in patients at disease onset also in the perspective of  
58  
59  
60

1  
2  
3 identifying those patients at a higher risk of evolution to definite MS. Indeed, a seminal  
4  
5 study showed that an abnormal pattern of cortical recruitment at disease onset could  
6  
7 contribute to identify those CIS patients evolving to definite MS after one year [39].  
8  
9

10 In conclusion, our observations contribute further to support the notion of plasticity  
11  
12 processes in CIS patients, which might counteract the cognitive consequences of diffuse  
13  
14 tissue damage and allow, at least temporarily, a preservation of their cognitive capabilities.

List of abbreviations: HC= Healthy controls; CI=Cognitively impaired; CP=cognitively preserved; MNI=Montreal Neurologic Institute.

A: Cognitive model of working memory used for dynamic causal modeling (DCM) analysis from Au Duong et al. [19]. B: Inter-group differences in effective connectivity in the working memory network during the Paced Auditory Serial Addition Test (PASAT). Dotted black lines show differences between cognitively impaired (CI) patients compared to cognitive preserved (CP) patients. Dashed black lines show differences between CI patients compared to both healthy controls (HC) and CP patients. See text for further results.

254x190mm (72 x 72 DPI)

Areas showing activations during the Paced Auditory Serial Addition Test (PASAT) in healthy controls (A) and patients at presentation with a clinically isolated syndrome suggestive of multiple sclerosis (B). Both groups recruited regions located in the frontal and parietal lobes as well as areas that are part of the working memory network, bilaterally ( $p < 0.001$  FDR-corrected,  $k = 20$ ). Images are in neurological convention (left is left).  
254x190mm (72 x 72 DPI)

A: Areas showing increased activations in patients at presentation with a clinically isolated syndrome (CIS) compared to healthy controls (HC); B: cognitively impaired (CI) patients compared to cognitive preserved (CP) CIS patients; and C: CI patients compared to HC during the Paced Auditory Serial Addition Test (PASAT) ( $p < 0.05$  FDR-corrected,  $k = 20$ ). Images are in neurological convention (left is left)  
254x190mm (72 x 72 DPI)
